Objective: To test whether more physiologically assessed hot flashes were associated with more connectivity in the default mode network (DMN), the network of brain regions active during rest. We particularly focus on DMN networks supporting the hippocampus as this region is rich in estrogen (E) receptors (ER) and has previously been linked to hot flashes.

Design: Women underwent 24 hours of physiologic and diary hot flash monitoring, functional magnetic resonance imaging (MRI), 72 hours of sleep actigraphy monitoring, a blood draw, questionnaires, and physical measures.

Setting: University medical center.

Patient(s): Twenty midlife women aged 40–60 years who had their uterus and both ovaries and were not taking hormone therapy (HT).

Intervention(s): None.

Main Outcome Measure(s): The DMN functional connectivity.

Result(s): Controlling for age, race, and education, more physiologically-monitored hot flashes were associated with greater DMN connectivity (beta, B [SE] = 0.004 [0.002]), particularly hippocampal DMN connectivity (B [SE] = 0.005 [0.002]). Findings were most pronounced for sleep physiologic hot flashes (with hippocampal DMN, B [SE] = 0.02 [0.007]). Associations also persisted controlling for sleep, depressive symptoms, and serum E2 concentrations.

Conclusion(s): More physiologically-monitored hot flashes were associated with more DMN connectivity, particularly networks supporting the hippocampus. Findings were most pronounced for sleep hot flashes. Findings underscore the importance of continued investigation of the central nervous system in efforts to understand this classic menopausal phenomenon. Hot flashes are the classic symptom of the menopausal transition, experienced by more than 70% of women at some point during the menopausal transition (1). Hot flashes are associated with impairments in quality of life (2), depressed mood (3), reported sleep disturbance (4), and possibly even poorer memory function (5). Hot flashes are a leading driver of medical treatment-seeking at midlife for women (6, 7).

Despite their prevalence and impact on women’s lives, the understanding of the physiology of hot flashes remains incompletely understood. Leading models conceptualize hot flashes as originating in the central nervous system (8), yet there has been limited data investigating relations between the brain and hot flashes. Some data support changes in brain regions associated with awareness of bodily sensation, such as the insula and prefrontal cortex, acutely during hot flashes and the involvement of brainstem areas in the triggering of hot flashes (9, 10). However, little research has investigated brain network differences associated with hot flashes.

Hot flashes occur in the context of estrogen (E) withdrawal, and the effects of E on brain structure and function in humans remains controversial (11, 12). However, some prior studies (13–15) have suggested decrements in verbal memory during the perimenopause, a time when hot flashes are common. Although subjective hot flashes have not been associated with cognitive function, physiologically-measured hot flashes and the default mode network

**Objective:** To test whether more physiologically assessed hot flashes were associated with more connectivity in the default mode network (DMN), the network of brain regions active during rest. We particularly focus on DMN networks supporting the hippocampus as this region is rich in estrogen (E) receptors (ER) and has previously been linked to hot flashes.

Hot flashes are the classic symptom of the menopausal transition, experienced by more than 70% of women at some point during the menopausal transition (1). Hot flashes are associated with impairments in quality of life (2), depressed mood (3), reported sleep disturbance (4), and possibly even poorer memory function (5). Hot flashes are a leading driver of medical treatment-seeking at midlife for women (6, 7).

Despite their prevalence and impact on women’s lives, the understanding of the physiology of hot flashes remains incompletely understood. Leading models conceptualize hot flashes as originating in the central nervous system (8), yet there has been limited data investigating relations between the brain and hot flashes. Some data support changes in brain regions associated with awareness of bodily sensation, such as the insula and prefrontal cortex, acutely during hot flashes and the involvement of brainstem areas in the triggering of hot flashes (9, 10). However, little research has investigated brain network differences associated with hot flashes.

Hot flashes occur in the context of estrogen (E) withdrawal, and the effects of E on brain structure and function in humans remains controversial (11, 12). However, some prior studies (13–15) have suggested decrements in verbal memory during the perimenopause, a time when hot flashes are common. Although subjective hot flashes have not been associated with cognitive function, physiologically-measured hot
flashes, particularly those occurring during sleep, have been linked to poorer verbal memory performance (5). Furthermore, brain regions involved in verbal memory including the hippocampus and prefrontal cortex are rich in E receptors (ER) (16, 17). Acute doses of E2 are associated with greater functional connectivity between the hippocampus and the prefrontal cortex (18).

The default mode network (DMN) is a recently discovered network of brain regions that are active during rest in the absence of external stimuli (19, 20). Activity of this neural network is distributed across brain regions and occurs spontaneously. Suppression of the DMN is associated with better memory formation, and less suppression of the DMN predicts poorer attention to later tasks (21, 22). The DMN appears to be involved in a range of psychiatric and medical conditions, and DMN hyperactivity appears characteristic of major depressive disorder (23).

We tested whether self-reported and physiologically assessed hot flashes were associated with altered functional connectivity in the DMN, particularly networks supporting the hippocampus. We hypothesized that a higher frequency of physiologically assessed (but not self-reported) hot flashes would be associated with greater functional connectivity in the DMN, particularly networks supporting the hippocampus. We tested these hypotheses in a sample of midlife women who underwent brain imaging and detailed ambulatory physiologic hot flash monitoring. Physiologic assessment of hot flashes is particularly important to testing relations between hot flashes and the brain, as prior work has indicated that it is physiologically-detected hot flashes rather than self-reported hot flashes that are most related to cognition (5) and peripheral nervous system physiology (24, 25).

MATERIALS AND METHODS

Study Sample

Twenty women who were a subsample of a larger parent study of 300 women focused on menopause and cardiovascular function underwent brain imaging. At study entry, 9 women reported having daily hot flashes and 11 reported having no hot flashes in the past 6 months. Parent study inclusion criteria included being age 40–60 years; having a uterus and at least one ovary; not pregnant; being late perimenopausal (amenorrhea, >2–<12 months) or postmenopausal status (amenorrhea, ≥12 months) in accordance with STRAW +10 criteria (26); without a history of heart disease, stroke, arrhythmia, or breast cancer; and not taking hormone therapy (HT), selective serotonin reuptake inhibitor/serotonin-norepinephrine reuptake inhibitor antidepressants, clonidine, beta blockers, calcium channel blockers, gabapentin, or insulin within 3 months. Additional criteria for inclusion in the brain imaging substudy included no metal in the body and no history of chronic migraines, concussion, stroke, brain injury, dementia, or Parkinson’s disease. Of the 20 women who underwent the brain imaging protocol, one woman completed only part of the imaging protocol due to time limitations and an additional subject experienced hot flash monitor failure; therefore 18 women are included in these analyses.

Design and Procedures

The parent study protocol included anthropometric measures, questionnaires, blood specimens, and a 3-day ambulatory hot flash and actigraphy sleep assessment protocol. Women in the brain imaging substudy additionally underwent magnetic resonance imaging (MRI) on a separate day. Procedures were approved by the University of Pittsburgh Institutional Review Board. All participants provided written informed consent.

Hot Flashes

Hot flash monitoring was conducted with an ambulatory sternal skin conductance monitor and an electronic diary. Sternal skin conductance was recorded with the VU-AMS monitor, a portable device worn in a pouch around the waist. This device measures sternal skin conductance sampled at 1 Hz from the sternum with a 0.5-V constant voltage circuit passed between two Ag/AgCl electrodes (UFI) filled with 0.05 M KCl Velvac-chol/glycol paste (27). Participants were instructed to avoid exercising and showering during monitoring. Physiologic hot flashes were classified by standard methods, with a skin conductance increase of 2 μmho in 30 seconds (28) flagged automatically by UFI software (DPSv3.6) and edited for artifact (29). Given that some women show submaximal hot flashes failing to reach the 2-μmho criterion (30, 31), all potential hot flash events were also visually inspected, and events showing the characteristic hot flash pattern of <2 μmho/30 s increase were coded as hot flashes. This coding has been shown to be reliable (κ = 0.86) (30, 31). A 20-minute lockout period was implemented after the start of the flash during which no hot flashes were coded. To report hot flashes, participants were instructed to [1] complete a portable electronic diary (Palm Z22; Palm, Inc.) during waking hours and [2] press event mark buttons on their wrist actigraph and hot flash monitor (waking and sleeping hours) when experiencing a hot flash.

MRI Acquisition

Imaging data were collected at the University of Pittsburgh Magnetic Resonance Research Center (MRRC) using a 3-T Siemens Trio machine and a 12-channel Siemens head coil. A standard high-resolution T1-weighted volumetric magnetization prepared rapid gradient echo scans (MPRAGE) sequence was acquired in axial orientation (160 slices, 256 × 240, 1 mm isotropic). For the resting state scan, T2*-weighted BOLD acquisition was done using a gradient-echo planar imaging sequence; TR = 2,000 milliseconds, TE = 34 milliseconds, matrix = 128 × 128 × 29, voxel size = 2 × 2 × 3 mm3, oblique axial acquisition, integrated parallel acquisition techniques = 2. Images were acquired during 5 minutes (150 volumes). Subjects were instructed to lie still with their eyes open, look at a fixation cross, think of nothing in particular, and not to fall asleep.

MRI Processing

A seed-based region of interest (ROI) analysis method was carried out in SPM8 (Wellcome Department of Imaging
Neuroscience, London, UK; http://www.fil.ion.ucl.ac.uk/spm). Resting state functional images were slice time corrected, realigned, normalized to MNI space (using the MPRAGE), spatially smoothed with a 6-mm kernel, and temporally band-pass filtered (0.009 of 0.08 Hz). Functional connectivity analysis was performed using a seed-driven approach with the Conn toolbox (32). A component-based noise correction method (aCompCor) was used to remove physiologic and other spurious sources of noise (33). In addition, significant principle components of the signals from white matter and cerebrospinal fluid regions were removed together with movement-related covariates. The REX (http://web.mit.edu/swg/software.html) was used to extract the primary eigenvariate time-series of each ROI and then the Conn toolbox was used to extract network connectivity strength for the DMN, using the ROIs defined by Tzourio-Mazoye et al. (34). These ROIs include the medial prefrontal cortex, anterior cingulate cortex, orbitofrontal cortex, superior frontal gyrus, midcingulate cortex, posterior cingulate cortex, precuneus, angular gyrus, thalamus, and hippocampus. A correlation map was produced for each subject by extracting the residual BOLD time course from the ROIs and computing Pearson’s correlation coefficients between that time course and the time course of all other voxels. Correlation coefficients were converted to normally distributed z-scores using Fisher’s transform. The mean DMN strength was defined as the mean z score across all nodes of the DMN. The mean hippocampal DMN score was the mean z score for connectivity between the hippocampus and all the other nodes of the DMN.

Sleep

Participants wore a wrist actigraph and completed a sleep diary each day during the monitoring period. Actigraphy data were collected with a Minimitter Actiwatch–2 (Respironics, Inc.) in 1-minute epochs and analyzed with the Actiware (version 6.0.1) software program. Sleep diary data for bedtime and rise time were entered for calculation of sleep-wake variables. Actigraphy outcome variables included total sleep time (within the bedtime and rise time interval), sleep latency (bedtime to first sleep period), wakefulness after sleep onset (total minutes of wakefulness between sleep onset and final wake time), and sleep efficiency (100% * total sleep time/time in bed). Participants also completed the Pittsburgh Sleep Quality Index (35), a well-validated questionnaire measure of sleep quality.

Covariates

Demographics, menstrual history, and health behaviors were assessed by questionnaires and interview. Menopausal status was obtained from reported bleeding patterns, categorized as perimenopausal (amenorrhea, >2–<12 months), or postmenopausal (amenorrhea, ≥12 months). Race/ethnicity was self-reported by the participant. Education was assessed as years of completed education and due to small cell sizes was classified as less than or more than a college degree for analysis. Depressive symptoms were assessed by the Center for Epidemiologic Studies Depression Scale (36) and trait anxiety via the Spielberger State-Trait Anxiety Inventory (37). Concentrations of E2 were obtained from a morning fasting blood sample and assessed using liquid chromatography–tandem mass spectrometry, with interassay and intra-assay coefficients of variation (CV) of 5.0% and 8.1%, respectively, and a lower limit of detection of 0.5 pg/mL.

Statistical Analysis

Variables were examined for distributions, outliers, and cell sizes. Average DMN was log and square transformed due to skew. To account for variations in monitoring times, hot flash rates were calculated, with the number of hot flashes (either physiologically-detected or self-reported) divided by monitoring time and standardized to a 24-hour period. Hot flash rates were set to 0 for women without hot flashes. Associations between hot flashes and DMN variables were tested in linear regression models, controlling for a priori selected covariates age, race/ethnicity, and education. Additional covariates depressive symptoms, trait anxiety, and E2 concentrations were separately added into multivariable models in secondary models. All tests were two-tailed with an alpha set to 0.05. Analyses were conducted using SAS v9.4 (SAS Institute).

RESULTS

Participants were on average 55 years old and approximately a quarter of the women were African American, with the remainder non-Hispanic white (Table 1). Most of the women (85%) were postmenopausal. Nine women reported having

hot flashes, yet on physiologic monitoring 15 women showed physiologic hot flashes, a finding that is consistent with prior findings that women tend to under-report hot flashes relative to physiologic monitoring (38). For the sample as a whole, women reported an average of two hot flashes/24 hours, and showed seven hot flashes/24 hours on physiologic monitoring.

We first tested the relation between hot flashes and DMN connectivity. More physiologic hot flashes were associated with greater total DMN connectivity, as well as greater hippocampal DMN connectivity (Table 2; Fig. 1; Supplemental Fig. 1, available online). Associations were most pronounced for the left hippocampus and for physiologic hot flashes occurring during sleep, and associations persisted after covarying for age, race, and education. We next examined relations between hot flashes and a priori selected frontal–hippocampal connectivity, finding that physiologically-monitored sleep hot flashes were positively associated with connectivity in five of the six regions in multivariable models (Table 3). No significant associations were observed between self-reported hot flashes and DMN connectivity.

Given that relations between hot flashes and DMN connectivity were observed most strongly for sleep hot flashes, we examined whether sleep characteristics accounted for observed relations. None of the relations between hot flashes and DMN connectivity were accounted for by the sleep variables assessed, including sleep time, sleep efficiency, wake after sleep onset, or questionnaire-sleep quality (e.g., relations between physiologic sleep flashes and DMN outcome controlling for actigraphy assessed sleep time, for total DMN: B [SE] = 0.01 [0.006], P=.048; hippocampal DMN: B [SE] = 0.02 [0.007], P=.01; left hippocampal DMN: B [SE] = 0.03 [0.009], P=.007). Notably, the sleep indices were weakly or largely unrelated to the DMN outcomes (data not shown).

We considered several additional analyses. In models of relations between physiologic hot flashes and DMN outcomes, we additionally adjusted for covariates such as depressive symptoms, trait anxiety, and serum E2 concentrations. Results were unchanged (data not shown).

### DISCUSSION

This study was the first to investigate the relation between menopausal hot flashes and resting state connectivity, showing that more physiologically-monitored hot flashes (but not self-reported hot flashes) were associated with greater activity in the DMN. Findings were most striking for DMN connectivity to the hippocampus. In addition, relations were most pronounced for physiologically-monitored hot flashes occurring during sleep as compared with waking.

The DMN is an organized network in the brain that is active during rest. Data indicate that hyperconnectivity and hyperactivity of the DMN, as well failure to deactivate components of the DMN, is associated with maladaptive emotional states such as major depressive disorder (23, 39). Elevated DMN activity has also been linked to rumination (23), and alterations in DMN activity have been linked to chronic pain (40) and possibly insomnia (41). It is notable that these findings were for physiologically-assessed hot flashes and not subjectively-experienced hot flashes, arguing against a purely symptom-perception or somatic focus explanation of links between hot flashes and the DMN. In addition, depressive and anxious symptoms were measured and did not account for observed associations. Notably, suppression of the DMN is associated with better memory formation (21, 22). However, why the DMN is linked to hot flashes is not entirely clear and requires further investigation.

The current study pointed to DMN connectivity to the hippocampus, in particular as related to hot flashes. A numerous literature indicates that the hippocampus may be sensitive to changing E levels in the menopause transition and possibly to hot flashes (42). The abrupt declines in endogenous E2 that mark the menopause transition may negatively impact the hippocampus, which is a region rich in ERs (16). Memory problems are a leading cognitive change that women report during the menopause transition; in one study (43) 60% of women transitioning through the menopause transition indicated that perimenopausal women who used HT had improved verbal

memory and increased activation in the left hippocampus during this memory task relatively to their counterparts who had never used HT (11). Furthermore, experimental suppression of the reproductive axis in young women results in changes in verbal memory encoding, which can be restored with restoration of ovarian function (44, 45). Finally, prior work has shown more overnight physiologic hot flashes related to poorer verbal memory function (5). This body of literature points to adverse changes in the hippocampus and all the other nodes of the default mode network. Our findings for hippocampal DMN connectivity and hot flashes are consistent with this work. However, it is notable that endogenous E2 concentrations, measured with state of the art methods, did not account for these relations, suggesting that other physiologic processes, such as hypothalamic-pituitary-adrenal axis activity linked to both hot flashes and hippocampal function, may be important to investigate in future research on hot flashes and DMN activity.

Findings were most pronounced for physiologically-monitored hot flashes, particularly hot flashes during sleep compared with those during waking hours. These findings are consistent with other research showing that physiologically-monitored hot flashes, rather than self-reported hot flashes, were associated with verbal memory (5). Physiologically-monitored hot flashes differ from self-reported hot flashes in several important ways. Like the results observed, most studies that use physiologic hot flash measures in the ambulatory setting detect more hot flashes than are reported (5, 25, 38). Although these measures merit continued refinement for use in large studies (46), physiologic hot flash measures for use in large studies (46), physiologic hot flash measures in the ambulatory setting depend on more hot flashes than are reported (5, 25, 38). Physiologic hot flash measures may be particularly useful for measuring hot flashes during sleep, when hot flash reporting may be particularly difficult and influenced by the quality of sleep itself (50, 51).

Notably, in the present study the strongest associations were for hot flashes detected during sleep. Why associations between hot flashes and DMN connectivity were most pronounced for sleep rather than waking hot flashes is not entirely clear, but these findings are consistent with prior work showing overnight hot flashes most related to verbal memory (5). The associations between sleep physiologic hot flashes and DMN connectivity were not accounted for by sleep characteristics such as sleep time, waking during the night, or subjective sleep quality, broadly consistent with prior work (5). In fact, sleep indices were weakly or unrelated to DMN connectivity in this study. Whether sleep hot flashes (aka “night sweats”) and waking hot flashes have different underlying physiologies is not known, although it is notable that other work has found that reductions in cardiac vagal control with hot flashes were particularly large for sleep physiologic hot flashes (25). Furthermore, investigation of the unique role of sleeping hot flashes in relation to brain function is warranted with more intensive measures (e.g., polysomnography) of sleep.

This study has several limitations. The main limitation of the study was its small size, which may have limited power to detect associations, although it is notable that such consistent findings were noted between DMN activity and hot flashes

Note: Covariates are age, race, education. DMN = default mode network; LH = left hippocampus; MCC = midcingulate cortex; MPC-ACC-OC = medial prefrontal cortex, anterior cingulate cortex, orbitofrontal cortex; RH = right hippocampus; RSFG = right superior frontal gyrus.

P < 0.10.

P < 0.05.

P < 0.01.

Figures 1

Scatterplot of relation between sleep physiologic hot flashes and hippocampal default mode network. Values of horizontal axis represent mean of the normalized correlations between the hippocampus and all the other nodes of the default mode network.

Despite this small sample. However, these findings should be replicated in future work. Primarily postmenopausal women were included here and thereby any differences by menopausal stage could not be investigated. Although the sleep measures used were extensive, future work should further expand the sleep battery given the particular importance of nocturnal hot flashes.

This study had several strengths. This is the first study to investigate resting state connectivity in relation to menopausal hot flashes. Hot flashes were investigated via rigorous methods: physiologic monitoring and prospective diary report and during wake and sleep as a woman went about her daily activity. These methods allowed investigation of any similarities or differences in the patterns of associations across indices and states. Sleep was measured by actigraphy, an improvement over prior work that has largely used self-reported sleep. In addition, other related important indices, including depression, anxiety, and rigorously-measured endogenous E2 concentrations were assessed and their roles considered.

In conclusion, more menopausal hot flashes were associated with greater DMN connectivity, particularly to the hippocampus. These associations were most pronounced for physiologically-monitored hot flashes occurring during sleeping hours. As opposed to prior work showing changes in brain function acutely during hot flashes, the current data support differences in DMN connectivity that distinguish women with varying degrees of hot flash burden. Most investigations have focused on peripheral physiology in attempting to understand the physiology of hot flashes. These findings underscore the importance of continued investigation of central nervous system function in considering the propensity toward and underlying physiology of hot flashes.
